Abstract
A vertical photobioreactor containing the microalgae Scenedesmus obliquus is a highly efficient system for converting carbon dioxide (CO₂) into biomass. The use of photobioreactor for CO₂ mitigation has been explored using microalgae as photosynthetic microorganism. The growth rate (µ h⁻¹) were 0.03; 0.13; 0.20; 0.09 at treatment of 0%, 2%, 5% and 7% pure CO₂ supplied, respectively during 16 days experiment. The maximum dried biomass (gr ml⁻¹) was 1.7 at 2% pure CO₂. The highest CO₂ removal efficiency (%) was 34 at 2% pure CO₂ supply. The results showed that the photobioreactor gave a high efficiency of CO₂ removal by phototrophic microalgae culture.

Keywords: vertical photobioreactor, CO₂ removal, microalgae, photosynthetic.

1. Introduction
Microalgae have a large biotechnological potential for producing valuable substances for the feed, food, CO₂ sequestration, cosmetic and pharmaceutical industries as well as for biotechnological processes. Two distinctive cultural systems have been proposed for CO₂ sequestration with microalgae. One is the open pond system, and the other is the closed photobioreactor system. There is ongoing discussion regarding whether the open pond system or the closed photobioreactor system would be better for CO₂ sequestration [1], [2], [3]. Apparent advantages for utilizing the open pond system are low initial and operational costs. On the other hand, a photobioreactor system has a higher potential productivity due to better environmental control and harvesting efficiency. Compared to open-air systems the PBRs have reduced risk for contamination, more controlled cultivation conditions, better possibility to cause strong turbulent flow, lower CO₂ losses, lower water evaporation, increased volumetric yield, better biomass quality, improved harvesting efficiency and increased illuminated area to volume ratio [4], [5], [6].

Technical systems for the production of phototrophic microorganism are termed photobioreactors (PBR). The design of the technical and technological basis for photobioreactors is the most important issues for economic success in the field of phototrophic biotechnology. For high-value products in particular, closed systems of photobioreactors seem to be the more promising field for technical development despite very different approaches in design [7]. Several types of photobioreactors have been reported, such as vertical tubular, flat and column photobioreactors. Vertical tubular-type photobioreactors, such as bubble and air-lift photobioreactors, have often been thought to achieve the most efficient mixing and the best volumetric gas
transfer [8]. The CO\textsubscript{2} transfer efficiency is one of the most important parameters for enhancing the CO\textsubscript{2} biofixation rate and algal productivity in a photobioreactor culture system [9]. The carbon dioxide mass transfer capacity of a photobioreactor is determined by the liquid-phase mass transfer coefficient and the specific area available for mass transfer [10]. For the purpose of mass transfer, the most frequently used approach is bubbling CO\textsubscript{2}-enriched air into the bottom of the photobioreactor with diffusers [8]. However, the associated drawbacks are a loss of CO\textsubscript{2} to the atmosphere and poor mass transfer rates because of the relatively low inter-facial specific surface area and the low residence times of the gas in the culture [3].

Photosynthesis is the basic process of microalgae-based carbon capture. To study such process a photobioreactor is designed. Photobioreactor is a device that can be used to provide optimum conditions for microalgae to facilitate the process of photosynthesis. In a photobioreactor light, temperature, pH, CO\textsubscript{2} and nutrients can be adjusted [11].

*Scenedesmus obliquus* ability to absorb CO\textsubscript{2} indicate that it was able to utilize CO\textsubscript{2} as an inorganic carbon source for growth [1], [3], [8]. In this study, the growth of phototrophic *Scenedesmus obliquus* as a group of microorganisms that use CO\textsubscript{2} as a source of energy shown by cell density, dry weight of microalgae biomass and chlorophyll content increasing at exponential phase. Carbon dioxide is the only carbon source for photosynthetic microalgae cultivation. When microalgae absorb CO\textsubscript{2}, they not only fix CO\textsubscript{2} but also grow in numbers yielding products such as carotenoids, pigments, proteins, and vitamins that are utilized to make nutraceuticals, pharmaceuticals, animal feed additives and cosmetics [9].

The objectives of this study were: (1) to develop vertical tubular photobioreactor; (2) to study the reflect operating condition and performance of photosynthetic *Scenedesmus obliquus*; and (3) to characterize the growth and CO\textsubscript{2} removal by *Scenedesmus obliquus* at different CO\textsubscript{2} levels.

### 2. Material and Methods

#### 2.1 Strain Microalgae and Artificial Growth

**Medium**

A Natural phototropic microalga which is *Scenedesmus obliquus* was isolated from Bojongsoang wastewater treatment plant, Bandung, Indonesia. Batch growth experiments were carried out in vertical photobioreactor as closed system were containing of 8 L Provasoli Haematococcus Medium (PHM) injected with various concentration of pure CO\textsubscript{2} gas (0%, 2%, 5%, 7%). Environmental conditions adopted were; 26°C temperature with light intensity of 2500 lux obtained from fluorescent lamp, 8 L min\textsuperscript{-1} of CO\textsubscript{2} flow rate, and 2% of pure gas CO\textsubscript{2} concentration.

#### 2.2 Vertical Photobioreactor System

Vertical bubble column photobioreactor is a vertical column either cylindrical or rectangular filled with growth medium and air was bubbled through a sparged system installed at the bottom. These systems have the highest gas hold up rates which means they have the best mass transfer compared to other systems [12], [13], [14]. CO\textsubscript{2} was injected from the bottom of the column to allow gas mixing with the medium. This is a low cost solution to obtain a high productivity. Sparger attached at the bottom of the reactor to convert the gas into small bubbles [15]. The photobioreactor with few modifications can be effective for commercial algal biomass multiplication, as well as having implied economic aspects [16]. Another advantage of vertical bubble column photobioreactor that it can be used on a large scale for the culturing of microalgae [17]. In this study, a vertical bubble photobioreactor, with the pore size diameter of sparger 160 μm, was specifically designed to explore the possibility of coupling CO\textsubscript{2} biofixation with microalgal growth. Pure CO\textsubscript{2} was used as feed gas to study the CO\textsubscript{2} removal and growth rate by *Scenedesmus obliquus* in a photobioreactor.

Photobioreactor was made of transparent material, in order to receive adequate lighting to achieve a high-density culture of microalgae. Thus, the efficiency of photosynthesis in an artificial environment is much higher than the natural environment. A schematic diagram of the vertical photobioreactor system is shown in Figure 1. The vertical photobioreactor was made of...
glass with a capacity of 10 L containing 8 L of constructed consortium culture (A). To achieve the objectives of this study, the photobioreactor was equipped with a source of gas from CO₂ gas cylinder (B) and aerator (C), biomass sampling port, gas outlet, and a port for the pH controller (G). Provisions were also made for the gas flowrate meter (D), CO₂ output sampling (E), silica gel tube (I), manometer (J), the photobioreactor base is equipped with a drain hole for the gas input and expenditure biomass (F), fluorescent lamp as the source artificial light (K) and pump (M). An outlet was provided in order to collect the samples for pH, biomass sample and CO₂ concentration measurements. A tubing intercept was provided between the flowrate meter and the inlet for inlet gas measurements, whereas the outlet gas was measured directly near the outlet provided for collecting the sample. The vertical photobioreactor was run in a continuous light mode day and night, with a constant supply of 0%, 2%, 5%, 7% pure CO₂ gas, respectively. Photobioreactor and all the accessories are assembled in such a way in a box iron frame covered by the board on all four sides, and fitted wheels to be easily moved. The inflow pure CO₂ gas was injected into the culture with various concentration 0%, 2%, 5% and 7%, respectively. Three probes for dissolved CO₂, dissolved oxygen (DO) and pH were installed at the top of the photobioreactor. The dissolved carbon dioxide, pH and DO of the algal culture were monitored online and recorded every minute by the controlling system. The choice of 10 L as photobioreactor volume was based on the following reasons, i.e.: 1) meet the needs of each sampling volume during the study period and 2) pay attention to the cost of making an artificial medium. Photobioreactor hydrodynamics aspects include: the dimensions of the tube are a total height of tube 80 cm, diameter 15 cm, height of liquid (growth medium) 65 cm; hose with a diameter of 15 mm for the flow of CO₂ and CO₂ gas cylinder from the aerator, CO₂ input into the holes located at the base of the reactor, sparger placed at the bottom of a vertical tube, precisely on the surface of the vent gas input (D), has an outside diameter of 25 mm, 21 mm in diameter and 100-160 μm pore diameter. Since the bubble have a small size, it become light and have a large surface. So, the bubble is easily broken to be well distributed along the reactor, from bottom to surface, instead of retained in the bottom of the reactor. The gas flow rate 8 L min⁻¹ was maintained at this level in order to keep the culture suspended in the medium. Position 4 TL lamps were uniformly positioned outside the photobioreactor so that they can be adjusted to obtain a light intensity of 2500 lux. The reactor is equipped with a coil on the outside of the tube to facilitate research on the impact of certain temperature stable during the study period.

Figure 1: Overview of vertical photobioreactor (not to scale).

2.3 Measurement of light intensity
A light sensor (TES1332A, Taiwan) was used to measure the light intensity on the surface of the bioreactor. The average light intensity was calculated by taking the weighted average of 60 measurements, which are located at the three horizontal planes uniformly located along the vertical axis of the reactor, and 20 evenly distributed measuring points along the radial axis for each horizontal plane height of the reactor [9].

2.4 Measurement of biomass concentration
The biomass concentration (g L⁻¹) was
measured by analyzing the optical density of the cell suspension at an absorbance wavelength of 665 nm using a spectrophotometer (thermo scientific type spectronic + 20, Germany). A calibrated straight line was obtained previously by plotting the A665 dry cell weight (g.L⁻¹).

2.5 Measurement of dry mass (suspended solids)
The dry mass of all the microalgae species was determined on triplicate culture samples. Suspended solids tests were conducted on microalgae culture, which was diluted to approximately 8 different optical density values. Equal volumes of the microalgae samples were filtered through a 47 mm Whatman® (Maidstone, England) GF/C glass micro fiber filter, which were previously ashed in an oven at 550°C for one hour and weighed for their initial weight. A suction pump was used to filter the samples and after filtration the filters were dried in a WTB Binder Laboratory oven made in Germany at 105-110°C for approximately 24 hours. The filter was taken and cooled to room temperature in a desiccator and was weighed to get the final weight [4]. The difference in the weights of the filter, after filtration and before filtration, divided by the sample volume filtered gave the dry mass. A plot of the optical density at 665 nm and dry mass in mg/l was developed.

2.6 Measurement of growth rate of the microalgae
A regression equation of the cell density and dry weight per liter of culture was obtained by a spectrophotometric method. Specific growth rate (μ) of microalgae is calculated by the following formula:

\[ \mu = \frac{N_t - N_0}{t - t_0} \times \frac{1}{N_t} \]  

(1)

Where, \( \mu \) = specific growth rate (cell biomass /ml/unit time); \( N_0 \) = Initial cell culture density at time \( t_0 \) (cell/ml); \( N_t \) = Culture density at time \( t \) (cell/ml); \( t-t_0 \) = time interval (day). Cell density (N) is obtained from calibration curve OD 665 vs X with a spectrophotometer.

2.7 Analysis of CO₂ and O₂ concentration
The CO₂ and O₂ concentration in the influent gas and effluent gas were measured 5 times per day by Portable Combination Gas Detector RIKEN Model RX-515. Measurements were performed to determine changes in the concentration of CO₂ in the gas holder with time, whereas the concentration of CO₂ dissolved in the culture medium was measured once a day using the Portable Carbon Dioxide Analyzer Oxyguard to know the solubility of CO₂ in the culture medium. From this measurement, the capability (efficacy) of the photobioreactor microalgae cultivation system as a CO₂ capture storage agent can be determined.

2.8 CO₂ removal efficiency
The CO₂ biofixation rate and the CO₂ removal efficiency were calculated by the following equations:

\[ CO₂ \text{ biofixation rate} = \frac{X_{max} - X_0}{t} \times C \times 44 \]  

(2)

\[ CO₂ \text{ removal efficiency} = \frac{Y_{in} - Y_{out}}{Y_{in}} \times 100\% \]  

(3)

where, \( X_{max} \) and \( X_0 \) are the maximum cell concentration and the initial inoculated cell concentration (mg/L); \( C \) is the carbon content of dried biomass analyzed by the elemental analyzer; 44 is the molecular weight of CO₂ and \( Y_{in} \) and \( Y_{out} \) are the CO₂ molar fractions in the inlet and outlet gas phases, respectively.

3. Result and discussion
3.1 Cell density
Figure 2 shows that cell densities in all the cultures increased up to day 8 for all pure CO₂ concentration input. On supply 0% CO₂, cell density decreased in 1-2 day culture period, but the next day the cell density increased although this increment was not as high as the culture with 2%, 5% and 7% CO₂ respectively. Treatment with 5% CO₂ produced a higher cell density compared to treatment with 0%, 2% and 7% CO₂. Each of the known photobioreactor types has some advantages as well as disadvantages. However, regardless of reactor design chosen, the same technical requirements must be met in order to achieve maximum growth of microalgae.
According to Kunjapur and Elridge [7], the ultimate goal of PBR design is to maximize the specific growth rate (μ) defined as "an increase in the mass of cells in culture per unit time per unit mass of cells." Specific growth rate (μ, h⁻¹) of Scenedesmus obliquus in the exponential phase ranging from the fastest to the slowest for 2% pure CO₂ supply, 5% CO₂ and 7% CO₂ and 0% were 0.2791; 0.2651; 0.1162 and 0.1038 respectively.

3.2 Dry biomass
Apart from observing the cell density, the growth response of Scenedesmus obliquus can be measured by weighing the dry biomass produced. Treatment with 0% CO₂ treatment did not produce any significant increase in biomass dry weight throughout the study period in all the cultures. There were fluctuations in the dry weight of Scenedesmus obliquus cultures. However, a decrease in the dry weight biomass was observed around day 8 or 9.

Treatment with 5% CO₂ input provides the highest dry biomass compared with treatment 2% and 7% (Figure 3). Maximum dry biomass average (gr/100 mL) at treatment supply 0%, 2%, 5%, 7% pure CO₂ were at 0.22; 1.69; 1.23 and 0.82 respectively. As photosynthetic organisms, microalgae are well adapted to capture ambient CO₂. Growing algae that capture ambient CO₂ will remove carbon dioxide and sequester it in the form of biomass [18].

3.3 Carbon dioxide removal efficiency
The amount of CO₂ absorbed (concentration in %) by microalgae obtained from the difference between the pure CO₂ injected into the photobioreactor with a CO₂ output out of the photobioreactor, taking into account the CO₂ dissolved in solution or culture growth medium. In this study, the CO₂ dissolved in the medium is very small and relatively constant throughout the study period. Scenedesmus obliquus can absorb 2% to 7% pure CO₂.

All cultures showed efficiencies above 10% for treatments with 2%, 5%, 7% CO₂ (Figure 4). Although microalgae are considered to be relatively efficient for capturing solar energy for the production of organic compounds via photosynthetic process, the photosynthetic efficiency of microalgae for the conversion of solar energy is typically below 20% [19], [20]. On the other hand, increasing the density of cultures decreases photon availability to individual cells, which reduces specific growth rate of cells. Therefore, the poor penetration of light could be the most significant limiting factor in microalgal cultivation. Chiu et al. [21] observed that the maximum efficiency of CO₂ removal was 63% (with 10% CO₂ in the aeration gas).

Figure 2 : Cell density of Scenedesmus obliquus (10⁶ cell.ml⁻¹) in each treatment of pure CO₂ supplies, room temperature (26 ±1°C), pH 7.14 ±0.31, flow rate of CO₂ 8 L.m⁻³, light intensity 2500 lux, photoperiodism light/dark (24 hours/0 hours)
3.4 Carbon dioxide fixation rate
According to an elemental analysis in the Scenedesmus obliquus cell at the end of cultivation, 1 g of biomass contained approximately 0.563 g carbon in the study. The value was used to estimate the CO₂ biofixation rate (mg.L⁻¹.day⁻¹). The CO₂ biofixation rate was calculated according to Equation 2, and the results are presented in Table 1. Figure 5 shows the CO₂ biofixation rate profiles of the Scenedesmus obliquus under different level of CO₂ concentration (%). Although the culture that was supplied with 7% CO₂ on day 3 had showed the highest of CO₂ fixation rate but the highest average of CO₂ fixation occurred in the culture that supplied with 2% CO₂ (-8.7 mg.L⁻¹.day⁻¹). The lowest biomass concentration and CO₂ biofixation rate were observed when the culture didn’t supply with CO₂.

4. Conclusion
Microalgae biofixation of CO₂ in photobioreactors has recently gained renewed interest as a promising strategy for CO₂ mitigation. Using a microalgal photobioreactor as a CO₂ mitigation system is a practical approach to the problem of CO₂ emission from waste gas. A vertical photobioreactor containing Scenedesmus obliquus is a highly efficient system for converting carbon dioxide (CO₂) into biomass. Scenedesmus obliquus were cultivated in a vertical photobioreactor input of 2%, 5%, and 7%, pure CO₂, all of them can grow well, which was observed by cell density, dried biomass and specific growth rate (μ). The highest CO₂ removal efficiency (%) was 34 at 2% pure CO₂. The results showed that the photobioreactor worked properly for CO₂ removal by phototrophic microalgae culture. CO₂ removal efficiency, CO₂ biofixation rate and specific growth rate will be improved in future studies, to examine the effects of temperature, light intensity and hydrodynamic aspects of photobioreactor.

Figure 3: Dry biomass of Scenedesmus obliquus in each treatment of pure CO₂ supplies, room temperature (26 ±1°C), pH 7.14 ± 0.31, flow rate of CO₂ 8 L.m⁻¹, light intensity 2500 lux, photoperiodism light / dark (24 hours/0 hours)
